Speech recognition systems typically use an acoustic model and a language model, and can be used to create applications that can interact in a natural way with a user. The acoustic model captures the acoustic aspects of speech, such as the vocal tract, mouth and lips, the spectrum of the audio stream and the prosody (e.g., pauses between words, volume, speech rate, etc.). The language model typically captures the semantics of a stream of words in a natural language, such as the probabilities of word combinations, for example: '"the cat sat on the mat"'. The speech recognizer system uses the two models to process an input stream, and produces a text transcription of the input that is then presented to the user. Speech recognition systems provide a text-to-speech function and a voice user interface that accepts speech input from a user and converts that to a text transcription, which the user can view or read. By adding an acceptance handler to an input stream, the text-to-speech function can read the stream of text. The user can then reply to the input, for example by pressing buttons on a keyboard, or by using a voice command to select options from menus. Speech recognition can be used for data entry, or by using a text-to-speech interface, a user can choose to just hear spoken input converted into a text transcription, or can read the transcriptions. Many text editors, such as vi and j, include a speech-recognition command which converts the text stream into a script, where the user can perform custom actions on it. A more advanced type of speech recognition is called conversational speech recognition, where a computer system can converse with the user. The underlying technology can be based on deterministic algorithms, such as HMM, or probabilistic algorithms, such as Gaussian Mixture Model, Hidden Markov Model, Neural Network, Support Vector Machine, or Large Margin Nearest Neighbour. Generally, conversational speech recognition systems can be regarded as a special case of a text-to-speech or voice user interface,

It is the standard in most programming languages to have variable scoping. This means that any variable declared in a particular scope has access to only the variables and functions that are declared in that scope. Take the following example: var x; function Func1() { var y; function Func2() { x=6;//Access to the x from the enclosing scope. } } function Func3() { x=7;//Access to the x from the enclosing scope. } Func1(); Func2(); Func3(); /* x = 6 Func1() Function: x = 6 Func2() Function: x = 7 Func3() Function: x = 7 */ However, if we change the x from 6 to 3 in the Func2 scope, then the program would print the following: Actual output Example 4 Here we can see that when the script is loaded, the x is a global (outside of any function). Once the page is parsed, the document.body is populated with a DOM element, and the x is now local to the document. When script is run, the variable x is shadowed by the new y. As you can see from the actual output above, the output is the same as the expected output. Example 5 And finally, here we see an example of a variable declared with var x = 0. With x declared, the scope is a function only
